# Wealth redistribution in bubbles and crashes<sup>\*</sup>

Li An<sup>a,\*</sup>, Dong Lou<sup>b</sup>, Donghui Shi<sup>c</sup>

<sup>a</sup> PBC School of Finance,

experienced a similarl spectacular ride between 2005 and 2009. Such repeated emergence of extreme price movements, accompanied b elevated trading volume, has long intrigued economists. Prior research has focused primaril on the formation of bubbles and possible triggers of crashes. Relativel little is known about the social economic impact of financial market bubbles and crashes.<sup>2</sup> A natural question arises: although bubble-crash episodes are often short-lived and full reversed, do the have long-lasting impact on our societ ?

We tackle this question b taking the perspectives of ordinar people—e.g., households, pensioners, savers—and examine a novel aspect of the social impact of financial markets: the wealth redistribution role of bubbles and crashes.<sup>3</sup> This is a meaningful empirical exercise for three reasons. First, relative to calm periods, it is less clear, ex-ante, who wins and who loses in bubbles and crashes. On the one hand, it seems natural that wealthier people—who are usuall more financiall sophisticated and less capital constrained—should outperform the less wealth in these tumultuous times. On the other hand, wealthier investors tend to accumulate risk securities in market booms (e.g., Hoopes et al., 2017), so ma suffer disproportionate losses in crashes.<sup>4</sup>

Second, bubble-crash episodes are almost alwa s accompanied b abnormall high trading volume and return volatilities; in the bubble-crash episode that we anal ze, for example, households churn their positions once ever three weeks (or nearl 18 times a ear). This extraordinar level of turnover, together with the abnormall high market and firm-specific volatilities, can give rise to wealth redistribution at an enormous scale.

The third and perhaps most important reason is that while bubble-crash episodes occur infrequentl in developed countries, the are much more common in developing economies.<sup>5</sup> This is all the more worr ing given the recent finding (e.g., Malmendier and Nagel, 2011) that salient, earl – ear experiences affect individuals' economic decisions decades later. Since the majorit of the population in developing countries are first-time investors in financial markets, these repeated occurrences of extreme price movements, albeit short-lived, can have long-lasting impact on the behavior and welfare of the hundreds of millions of households in these countries.<sup>6</sup>

Two recent empirical studies (Bach et al., 2020; Fagereng et al., 2020), using annual administrative data of household holdings from Northern European countries, have shown that the rich indeed get richer through financial investments. However, the low-frequenc nature of the data makes them less-suited to stud wealth redistribution in bubbles and crashes. For one thing, bubbles can emerge and turn into crashes quickl . Second, as emphasized alread , bubbles and crashes are accompanied b elevated levels of trading activit . As a result, observing household holdings with annual snapshots ields at best an incomplete (if not misleading) picture of the impact on wealth redistribution.

We contribute to the discussion of the wealth redistribution role of bubbles and crashes b exploiting *daily* administrative data from the Shanghai Stock Exchange (SSE) that cover the *entire* investor population of roughl 40 M accounts. Despite being the world's fourth largest stock market (behind the NYSE, Nasdaq and Tok o Stock Exchange), the SSE—like other emerging financial markets—is dominated b retail investors; during our sample period, nearl 90% of the trading volume is contributed b retail accounts. Compared to data used in prior studies, our administrative data offer two important advantages. First, our data contain individual accounts' holdings and trading records at a dail frequenc . Second, the holdings of all investors in our sample sum up to exactl each firm's total tradable shares; likewise, the bu and sell transactions in our sample sum up to the dail trading volume. The granularit and completeness of our data enable us to track the exact amount of capital flows across different investor groups in this market in each da , as well as the resulting gains and losses.

Our main sample covers an extraordinar 18-month period—from Jul 2014 to December 2015—during which the Chinese stock market experienced a rollercoaster ride: the Shanghai Composite Index climbed more than 150% from the beginning of Jul 2014 to its peak at 5166.35 on June 12th 2015 (including a mild increase from Jul to October 2014 and a rapid rall from October 2014 to June 2015), before crashing 40% b the end of December 2015. For comparison, we repeat all our anal ses using the two-and-half ears prior to June 2014, during which the market is relativel calm (as shown in Appendix Fig. A1). Together, our four- ear sample with granular observations allows us to carefull anal ze the impact of financial investment on wealth redistribution during bubble-crash episodes, and to contrast that with similar impact in calm periods.

<sup>&</sup>lt;sup>2</sup> A popular view in prior literature is that financial markets are a side show that has a negligible impact on the real econom (e.g., Morck et al., 1990; Blanchard et al., 1993).

<sup>&</sup>lt;sup>3</sup> Just like prior studies on the wealth effect of financial investment (e.g., Bach et al., 2020; Fagereng et al., 2020), our aim here is to quantif the gains and losses to different investor groups. Put differentl, we do not intend to provide an explanation for the price movements in these episodes, which we argue is orthogonal to our calculation of wealth redistribution. Consequentl, and following prior research, we take price movements as given throughout the paper.

<sup>&</sup>lt;sup>4</sup> For example, Sir Isaac Newton, one of the greatest scientists in human histor and a lifelong investor, took an aggressive bet near the peak of the South Sea Bubble and lost his lifetime savings of £20,000 in the crash (worth over £3M toda ). Irving Fisher, one of the greatest American economists, lost ever thing in the Crash of 1929 after infamousl predicting a few da s beforehand that stock prices had "reached what looks like a permanentl high plateau."

<sup>&</sup>lt;sup>5</sup> The surge in trading volume (on retail platforms such as the Robinhood app) and market volatilities in the US stock market during the Covid-19 pandemic suggests that our results are also relevant for developed markets. See, for example, https://www.wsj.com/articles/ from-1720-to-tesla-fomo-never-sleeps-11594994422.

<sup>&</sup>lt;sup>6</sup> See Badarinza et al. (2016) and Badarinza et al. (2019) for a literature review of household finance in emerging economies.

For ease of presentation and following the definition used b the China Securities Regulator Commission, we categorize all household accounts into four groups based on their initial account value with cutoffs at RMB 500 K, 3 M, and 10 M.<sup>7</sup> For the boom-bust period, the bottom group includes 85%, and the top group 0.5%, of all household accounts in our sample and are the focus of this paper. Despite the orders-of-magnitude difference in the number of accounts, the top and bottom groups have similar initial aggregate wealth in the stock market.

We find strong evidence that large investors gain while small investors lose in our bubble-crash episode. Specificall, the bottom 85% households lose 250B RMB due to active trading (i.e., relative to a bu -and-hold strateg) from Jul 2014 to December 201

### 2. Related literature

Our paper contributes to the debate on the real effect of financial markets. A popular view in prior literature is that financial markets are a side show that has negligible impact on the real econom . Morck et al. (1990) and Blanchard et al. (1993) argue that fluctuations in stock valuation do not affect real investment. This view seems naturall applicable to bubble-crash episodes. Take the Internet bubble for example, b the end of 2000, the Nasdaq index fell virtuall to its prebubble level; the increased investment in the tech sector during the four ears of the Internet Bubble is largel consistent with improved productivit in the sector (see, e.g., Pástor and Veronesi, 2009). Our paper contributes to this literature b examining a novel aspect of the social-economic consequences of financial market bubbles and crashes—how these periods of extreme return volatilities and trading volume affect the distribution of financial wealth, which can have long-lasting impact on man facets of the societ .

Our paper also sheds light on investor portfolio choice during bubbles and crashes.<sup>8</sup> Brunnermeier and Nagel (2004), Greenwood and Nagel (2009), Griffin et al. (2011) and Liao and Peng (2018) show that more sophisticated investors ride the bubble and get out of the market shortl before the crash, while less sophisticated investors get into the game too late and appear to be the ones driving the overshooting. Recent studies, for example, Dorn and Weber (2013) and Hoopes et al. (2017), using proprietar data in German and the US, respectivel, find that the wealth (the poor) tend to be net sellers (bu ers) of stocks during the 2008 global financial crisis. While our results on investor trading behavior confirm these prior findings, our focus is squarel on the wealth redistribution between the poor and wealth using our comprehensive dail holdings and transaction data.<sup>9</sup> Note that although we focus on one specific instance of bubble-crash episodes (like most prior empirical studies in this literature), the richness of our data allows us to a) compare the gains and losses across investor groups, b) examine the mechanisms that drive wealth redistribution, and c) most importantl, uncover a novel amplification of skill heterogeneit and wealth redistribution during extreme market conditions, which can have broader implications for other time periods and financial markets.

Our paper is also related to the recent empirical literature on return differentials between the poor and wealth (especiall the ultra-wealth) in financial markets. Bach et al. (2020) and Fagereng et al. (2020), using annual administrative data of household portfolios in Northern European countries, find that the wealthiest 1% of the population earn an annual investment return that is more than a full-percentage point higher than the rest of the population. Given the low-frequenc nature of the data, these studies focus on bu -and-hold portfolio returns in each ear over a long period of time, with the assumption that investors trade once a ear on December 31st. Campbell et al. (2019), exploiting monthl household stock market investment data from India, also show that the rich get richer (and the poor become poorer) due to differences in portfolio diversification.<sup>10</sup> Our stud complements this literature b examining the degree to which investment returns drive financial wealth inequalit in bubble-crash episodes.

Our results also contribute to the debate on stock market participation. One of the most robust findings across developed and developing nations is that although the stock market offers a high average return and has a low correlation with the rest of a t pical household portfolio, man households have been reluctant to invest in the stock market (e.g., Haliassos and Bertaut, 1995; Barberis and Thaler, 2003). Consequentl, polic makers in man countries, especiall those in developing nations, have been pushing for greater stock market participation (or more inclusive financial markets). Our results call for a re-evaluation, or at least rethinking, of such policies. On the one hand, passive investment in the stock market is potentiall beneficial to an one—even those with low financial literac, as it allows investors to earn the equit risk premium. On the other hand, households in developing markets tend to be active investors, like the 40 M household accounts in the Chinese market; consequent , greater market participation, if not managed proper , can be detrimental to individual welfare.

Finall, our stud contributes to the recent discussion of rising wealth inequalit . Atkinson et al. (2011), Alvaredo et al. (2013, 2018), Pikett (2014, 2015), and Pikett et al. (2019) provide compelling evidence of a worldwide surge in wealth concentration in the last fift ears.<sup>11</sup> The rise in wealth inequalit can be in part due to an increase in income disparit, but it ma also be driven b bequests and b heterogeneous returns from financial investments. To the extent that stock wealth and total wealth are positivel correlated, our results provide further evidence for this capital-investment channel. The ultra-wealth, those in the top 0.5% of the wealth distribution in the stock market, likel have better access to both information and capital than the rest of the market; consequentl, the enjo a disproportionate share of the total return on capital. The main takeawa of our paper is that this effect is greatl amplified in financial bubbles and crashes (when market volatilities and trading volume peak), leading to an even higher degree of wealth concentration.

<sup>&</sup>lt;sup>8</sup> More generall, our results are related to the vast literature on investors' trading behavior and common mistakes in their trading decisions in financial markets (e.g., Odean 1999; Calvet et al., 2007, 2009a, 2009b; Chen et al., 2019; Cai, He, Jiang, and Xiong, 2020; Li et al., 2021).

<sup>&</sup>lt;sup>9</sup> That prior researchers are onl able to observe a non-representative subset of the investor universe (be it hedge funds, mutual funds or households), or a part of their transactions (sells but not bu s) makes it difficult, if not impossible, to anal ze the issue emphasized in this paper.

<sup>&</sup>lt;sup>10</sup> Relatedl, Barber et al. (2009) show that retail investors in aggregate lose to institutions in the setting of the Taiwan Stock Market. Sakong (2019) provides evidence that relative to wealth household, poor households "bu high and sell low" in the housing market, which contributes to increasing wealth inequalit in the US.

<sup>&</sup>lt;sup>11</sup> Both the popular press and academic research have linked this widening wealth inequalit to adverse social outcomes, including social unrest, political populism, regional crimes, and mental health issues (e.g., Pickett and Wilkinson, 2019).

## 3. Institutional background and data descriptions

The last two decades have witnessed tremendous growth in the Chinese stock market. As of June 2015, the total market capitalization of China's two stock exchanges, Shanghai Stock Exchange (SSE) and Shenzhen Stock Exchange (SZSE), exceeded 10 trillion USD, second onl to the US. Despite this unparalleled development, China's stock market has much in common with other developing markets. For example, it remains dominated b retail investors; according to the official statistics released b the Shanghai Stock Exchange, retail trading accounted for over 85% of the total trading volume in 2015 (which we confirm in our data). Given the striking similarities between the Chinese stock market and other developing markets (in terms of retail ownership, trading activities, regulator environments, etc.), we believe that our results have broader implications for emerging economies. As such, our exercise provides a useful first step to understanding the heterogeneit in household experience during these tumultuous periods.

#### 3.1. Data sources and summary statistics

We obtain dail administrative data from the Shanghai Stock Exchange, which cover the entire investor population of around 40 M accounts. More specificall, our account-level data are compiled b the China Securities Depositor and Clearing Corporation (CSDCC) and are sent to the Exchange at the beginning of each trading da . The data are kept on the Exchange's internal servers for record keeping purposes. Relative to the data used in prior studies, our regulator bookkeeping data offer two important advantages. First, our data contain individual accounts' holdings and trading records, at the firm level, at a dail frequenc .<sup>12</sup> Second, the holdings of all investors in our sample sum up to exactl each firm's total tradable shares; the bu transactions and sell transactions in our sample also sum up to the dail trading volume in the Exchange.

For ease of computation and presentation, we aggregate the 40 M accounts in our sample into various investor groups. At the broadest level, we classif all accounts into three categories: those owned b households, institutions, and corporations. (Account t pe and ownership information is directl observable in our administrative data.) The last categor includes both cross holdings b other firms and ownership b government-sponsored entities. Household accounts are further stratified into four groups based on account value (defined as the sum of equit holdings in both Shanghai and Shenzhen stock exchanges and cash in the account) with the following cutoffs: below

## Summar Statistics

Panels A, B, and C present summar statistics on account value, trading volume, and initial portfolio tilts b different investor groups in the bubblecrash period. The entire investing population is classified into three broad categories: households, institutions, and corporations. Within the household sector, investors are further classified into four groups according to their total account value (equit holdings in both Shanghai and Shenzhen Stock Exchanges + cash value); WG1 to WG4 include investors whose total account value fall into the brackets of <500K, 500K-3M, 3M-10M, and >10M, respectivel . Panel A reports summar statistics on account value and trading volume (in billions of RMB). The initial account value and capital weight are calculated on Jul 1<sup>st</sup>, 2014. The average account value and trading volume refer to the time series average in our entire sample period. Panel B shows portfolio st le stilts of different household wealth groups at the beginning of our sample. Specificall , we regress stock-level portfolio weights of each household group – adjusted b the portfolio weights of the entire household sector – on beta, firm size (size), and book-to-market ratio (bm). Panel C shows the weekl pairwise correlations in trading, defined as the net trading in individual stocks divided b the number of shares tradable, of each household group as well as that of mone managers (mutual funds plus hedge funds), averaged across our sample period. Panel D provides an approximate mapping between equit wealth and total wealth using data from the 2014 surve of the China tradable, of each household group as well as that of professional mone managers, averaged across our sample period). We discuss these summar statistics in greater details in Section 1.1 of the Online Appendix.

### 3.2. Data limitations

Our data also have several limitations. First, we do not observe households' wealth allocations in other markets, such as real estate and bank savings products. Although direct equit holdings are onl one component of total household wealth, it is likel that total wealth and equit wealth are positivel correlated. Data from the 2014 surve of the China Famil Panel Studies (CFPS), conducted b the Institute of Social Science Surve at Peking Universit, confirm a correlation between total wealth and equit wealth of 0.46 and an elasticit of total wealth to equit account value of 0.15 among market participants in the Chinese econom .<sup>14</sup>

We also provide an approximate mapping between the distribution of equit wealth held b Chinese households and that of their total net wealth, using data from the 2014 CFPS and estimates of the wealth distribution in China b Pikett et al. (2019) (as shown in Table 1 Panel D and described in Section 1.2 of the Online Appendix). Two facts are worth pointing out here. First, stock market participants are drawn from the whole distribution of household wealth. For example, nearl half of stock investors are from the bottom 80% of the wealth distribution. Second, given the positive correlation between equit wealth and total net worth, the 0.5% threshold in the equit wealth distribution (the focus of this paper) corresponds roughl to the 0.1-0.01% cutoff in the total wealth distribution.

Second, and relatedl, we do not observe households' holdings of equit mutual funds. This is not a major concern for our purpose because during our sample period mutual funds hold 3% of the equit market and account for less than 3% of the trading volume (in comparison, retail investors contribute nearl 90% of the trading volume). Third, we do not have information on margin borrowing b individual accounts. This, however, does not impact our calculation of gains and losses in RMB terms experienced b different investor groups. Finall, we do not observe holdings and transactions in stock index futures. However, the futures market is dominated b a small number of large institutions so has little impact on the majorit of Chinese household investors.

#### 4. Wealth redistribution in a bubble-crash episode

Conceptuall, each investor's (or investor group's) end-of-period stock market wealth can be decomposed into four parts: a) initial stock holdings at the beginning of our sample; b) capital flows into and out of the stock market (i.e., through trading) in our sample period; c) initial-holdings-generated gains and losses following a bu -and-hold strateg (which are equal to initial holdings multiplied b subsequent cumulative returns); and d) capital-flow-generated gains and losses (which are the sum of each RMB invested multiplied b its corresponding cumulative return from the da of investment to the end 2015, see Eq. (5)).

It is useful to note that bu -and-hold strategies (corresponding to component c) above) are not a zero-sum game. In the classic CAPM framework, for example, all investors hold the market portfolio and earn the market return, which is on average positive. In other words, component c) can be positive for all investors as the market value grows. In our data, household groups hold similar stock portfolios at the beginning of Jul 2014, so there is little variation in their initial-holdings-generated gains and losses (which are largel determined b the market return in our sample period). In contrast, active trading (corresponding to component d) above) is a zero-sum game – if someone is bu ing, someone else is selling. In other words, flow-generated gains sum up to exactl zero if the flows (or trading) sum up to zero. (In practice, investor trading does not alwa s sum up to zero because of share issuance and conversions of non-tradable to tradable shares.)

Consequentl, we focus on gains and losses resulting from households' trading activit (component d) in the above decomposition) throughout this paper, and interpret them through the lens of wealth redistribution. More specificall, we emplo two benchmarks to evaluate households' trading activit and the ensuing gains and losses. The first benchmark is a bu -and-hold investor with the same initial holdings as the household group in question. The second benchmark assumes that household groups' trading is proportional to their initial capital weights.

#### 4.1. Capital flows by different investor groups

We start b comparing each investor group to a bu -and-hold investor with the same initial holdings in the stock market; that is, we focus on the trading activit of each investor group. Trading in (or capital flow to) each stock s b investor group g on da t is calculated as the value of the stock holding at the end of da t minus that at the end of da t-1 multiplied b

<sup>&</sup>lt;sup>14</sup> We follow Campbell, Ramadorai, and Ranish (CRR, 2019) to estimate the correlation and elasticit of total wealth to equit account value; CRR (2019) report a correlation of 0.3 and an elasticit of 0.15 among Indian stock holding households in 2012. The CFPS surve in China does not collect information on the value of equit holdings; instead, it asks for the value of all financial products (including stocks, mutual funds, bonds, other derivatives, etc.); stocks holdings are b far the most common form of household financial investment reported in the surve , and for more than half of the surve respondents the onl form of financial investment.

**Fig. 2.** Cumulative Flows of Households in the Bubble-Crash Period. This figure shows cumulative capital flows b different wealth groups in the household sector. The top figure shows the raw value of flows, and the bottom figure shows adjusted flows. Households are classified into four groups according to their total account value (equit holdings in both Shanghai and Shenzhen Stock Exchanges + cash value), with cutoffs at RMB 500 K, 3 M, and 10 M. WG1 includes investors with account value greater than 10 M. In the bottom figure, we adjust the raw value of flows of each group in each da b subtracting a fixed fraction of the capital flow of the entire household sector, where the fraction is equal to the capital weight of that group at the beginning of the sample (see Eqs. (3) and (4)). Capital flows are in billions of RMB, and are plotted against the right -axis.

shares part to smaller households and part to corporations. In the bust period of June to December 2015, the four groups have cumulative capital flows of 32B, -137B, -196B, and -473B RMB, respectivel.

One potential concern with the wa flows are constructed is that the four household groups have different aggregate equit wealth to start with. Even if all households have the same trading propensit, we ma mechanicall observe different trading activities because of the differences in their initial wealth in the equit market. To address this, we emplo a second benchmark, the proportional-trading benchmark, in which we compare the trading activit of each household group with

a fraction of the aggregate trading b the household sector where the fraction is proportional to the initial equit -wealth share of the household group in question. For example, the top wealth group accounts for 26.5% of the total equit wealth of the household sector at the beginning of our sample, we then subtract in each da the trading activit of the top wealth group b 26.5% of the aggregate trading of the household sector. We label this difference the *adjusted flow*. The adjusted flow b household group g in stock s is then defined as:

$$adj_flow_{g,s,t} = flow_{g,s,t} - \omega_g \sum_g flow_{g,s,t},\tag{3}$$

where  $w_g$  is the initial wealth weight in the equit market of household group g, which sums up to one across the four groups. Adjusted flows therefore capture excess relocation into and out of each stock and, b construction, sum up to zero across household groups ever da . Summing over all stocks in the market, we have

$$adj_flow_{g,t} = \sum_{s} Adj_flow_{g,s,t}.$$
(4)

The bottom panel of Fig. 2 shows the cumulative adjusted flows to the market b different household groups. Again, there is a *positive* monotonic relation between account value and adjusted flows. The wealthiest group of households are net bu ers, while the smaller households are net sellers, of stocks during the bubble period. The cumulative adjusted flows of the wealthiest (WG4) and second wealthiest (WG3) groups peak on June 8th and Ma 25th, 2015

**Fig. 3.** Flow-Generated Gains of Households in the Bubble-Crash Period. This figure shows cumulative flow-generated gains b different wealth groups in the household sector. The top figure shows flow-generated gains/losses, and the bottom figure shows adjusted-flow generated gains/losses. Households are classified into four groups according to their total account value (equit holdings in both Shanghai and Shenzhen Stock Exchanges + cash value), with cutoffs at RMB 500, 3, and 10 M. WG1 includes investors with account value less than 500 K, and WG4 includes investors with account value greater than 10 M. We calculate the cumulative (adjusted-) flow-generated gains of each household group b multipl ing dail flows to a stock with the subsequent stock return (till the da in question), and then summing this up over all da s till the da in question and across all stocks in the household portfolio (see Eqs. (5) and (6)). Capital gains are in billions of RMB.

are then calculated as the product of dail flows and subsequent market returns. Specificall, the cumulative flow-generated gain driven b market-level flows up to da t for investor group g is equal to

$$cum\_flow\_gen\_gains_{g,t}^{mkt} = \sum_{\tau \le t} flow_{g,\tau} \times ret_{\tau,t}^{mkt}$$
(7)

#### Summar of Capital Flows and Flow-Generated Gains

Panel A of this table reports capital flows (Panel A1) and flow-generated gains (Panel A2) of different household wealth groups in the bubble-crash period. Within the household sector, investors are classified into four groups according to their total account value (equit holdings in both Shanghai and Shenzhen Stock Exchanges + cash value); WG1 to WG4 include investors whose total account value fall into the brackets of <500K, 500K-3M, 3M-10M, and >10M, respectivel . For comparison, Panel A3 shows cumulative flow-generated gains of various household wealth groups in the two-and-half ears prior to our main sample (201201 to 201406), during which the market is relativel calm.

Panel B reports aggregate capital flows (Panel B1) and flow-generated gains (Panel B2) for the three sectors: households, institutions, and corporations, as well as those of mutual funds and state-owned corporations. Both capital flows and flow-generated gains are in billions of RMB.

Panel A1. Capital flows (Bil. RMB)         boom period (140701-150612)         flow into the market       -128       280       282       709         adjusted flow into the market       -460       -45       98       406         bust period (150612-151231)		WG1	WG2	WG3	WG4

where  $flow_{g,\tau}$  is the market-level capital flow of group g in da  $\tau$ , and  $ret_{\tau,t}^{mkt}$  is the cumulative market return between  $\tau$  and t. Similarl, cumulative adjusted-flow-generated gains are calculated as

$$cum\_adj\_flow\_gen\_gains_{g,t}^{mkt} = \sum_{\tau \le t} adj\_flow_{g,\tau} \times ret_{\tau,t}^{mkt}$$
(8)

The top panel of Fig. 4 shows the market-level cumulative flow-generated gains for the four household groups sorted b account value: during this one-and-half- ear period, the four household groups accumulate total capital gains of -118B, -28B, 16B, and 84B, respectivel. After adjusting for the part of flows that is proportional to the group's initial capital weight, the bottom panel of Fig. 4 shows the corresponding cumulative adjusted-flow-generated gains for the four household groups: -104B, -15B, 23B, and 96B, respectivel. In sum, about 40% of the total wealth redistribution (100B/250B) between the largest and smallest household groups is attributable to flows into and out of the market as a whole, while the remaining 60% to the heterogeneit in portfolio composition.<sup>19</sup>

For ease of comparison, Table 2 Panels A1 and A2 list all the aforementioned quantities of capital flows and flowgenerated gains for the four household groups over various horizons. We further classif household accounts into two cat-

<sup>&</sup>lt;sup>19</sup> Since we do not observe households' other investments, we are unable to calculate the benchmark return earned b households in other markets, so ma over- or under-state households' gains from market timing.

Fig. 4. Flow-Generated Gains at the Market Level in the Bubble-Crash Period. This figure shows cumulative flow-generated gains at the market level b

Kaustia and Knüpfer, 2012). Second, existing accounts and new entrants exhibit one common pattern: within either categor, relative to smaller accounts, larger accounts increase their risk equit holdings in the boom period and reduce their equit holdings in the bust period. Panel A2 further shows that existing accounts contribute roughl two thirds of the total wealth redistribution between the top 0.5% and bottom 85% of households, while new entrants contribute the remaining one third.

Table 2 Panel A3 shows wealth redistribution across households in a period of a relativel calm market, from Januar 2012 to December 2014. (The cumulative gains and losses to each household wealth group during this period are also plotted in Fig. 5.) As is clear from the table and the figure, the gains and losses to the four household wealth groups in the calm period are an order of magnitude smaller than those in the bubble-crash episode. For example, in an 18-month subperiod in the two-and-half ears prior to June 2014, the ultrawealth (those in the top 0.5% of the equit wealth distribution) have a gain of at most 8B (21B) RMB under the bu -and-hold (proportional-trading) benchmark. These figures amount to 1 and 3% of the initial equit wealth held b the top household group (compared to the 30% gain between Jul 2014 and December 2015). We observe losses of similar magnitudes experienced b the bottom household wealth group in this period.

In Panel B of Table 2, we report flows and flow-generated gains for the three investor sectors. Corporate investors had a collective outflow from the stock market of 126B RMB in the boom period and an inflow of 952B RMB in the bust period, and had a total trading gain of 113B RMB (75B b state-owned corporations). This is expected, as the "national team" went in near/at the bottom of the market to put a backstop on investors' fire sales. Just like the Fed and the US Treasur that ended up registering a gain from their bailout programs in the Global Financial Crisis (e.g., Calomiris and Khan, 2015), the Chinese "national team" also made a profit b providing much-needed liquidit to constrained investors.

Institutional investors had a collective inflow of 78B RMB in the boom period and a further inflow of 138B in the bust period, and had a total gain of 252B RMB from trading. The household sector as a whole had an inflow to the market of 1142B RMB in the boom period, an outflow of 775B in the bust period, and a total trading gain of 6.7B RMB in this 18-month period. Appendix Fig. A2 plots the flow-generated gains of the three investor sectors.

The sum of the trading gains across the three investor sectors is over 370B RMB in this period. The reason that it is not zero is because trading b the three investor sectors does not alwa s cancel out;

**Fig. 5.** Flow-Generated Gains of Households in Calm Market Conditions. This figure shows cumulative flow-generated gains b different wealth groups in the household sector for the period Januar 2012 to June 2014, during which the market is relativel calm. The top figure shows capital gains generated b the raw value of flows, and the bottom figure the adjusted flows (calculated using Eq. (3)). Households are classified into four groups based on their total account value at the end of December 2011 following the procedure described in Section 3. We calculate the cumulative (adjusted-) flow-generated gains of each household group b multipl ing dail flows to a stock with the subsequent stock return (till the da in question), and then summing this up over all da s till the da in question and across all stocks in the household portfolio (see Eqs. (5) and (6)). Capital gains are in billions of RMB.

more easil move capital into the stock market during the boom period. In sum, roughl half of the wealth redistribution at the market level can be explained b differences in timing abilit and the other half b the wealth 's overall larger exposure to the stock market.

In Online Appendix Table A3, we classif all household accounts into those that exist before Jul 2014 and new entrants after Jul 2014. We again observe monotonic relations between portfolio alpha and account value, and between market beta and account value. One interesting observation is that for accounts that exist before Jul 2014, all wealth groups have

Market Timing: A Portfolio Approach This table reports regression results of dail returns to a held b different household wealth groups on contempo levered portfolio is constructed b assuming a) ever in the stock market (i.e., stock wealth equals the tot then either borrow at the risk free rate to fund fu ceeds from selling stocks in risk free assets; b) ey market tracks the market index. Panel A. Bubble-crash period: 2014 Jul. - 26 Levered portfolio return: tock market pecificall , the

B, the relation completel reverses in the bust period: the wealthier groups now reduce their market exposures b moving out of high-beta stocks, while the smaller groups increase their holdings in high-beta stocks.

Fig. A3 plots the time variation in average portfolio betas of the top and bottom household groups. To make the portfolio beta comparable across time, in each week, we subtract from each group's portfolio beta the wealth-weighted average beta of the entire household sector. As can be seen from the figure, the wealthiest group (with the lowest portfolio beta to begin with) start increasing their market exposures earl in the boom period and aggressivel reduce their market exposures short1 after the market peak. All the other three household groups exhibit the opposite trading pattern. For reference, we also plot the imputed leverage ratios of the top and bottom household groups (based on the exercise in Section 2 of the Online Appendix). Not surprisingl , there is a strong correlation between the imputed leverage ratio of the household group portfolio.

Before moving on to discuss the return predictabilit of household trading, we wish to highlight a few additional observations from Table A4—the relations between stock-level trading and other firm characteristics. First, during the boom period, largest households are net bu ers of large-cap, value, and marginable stocks while smallest households are net sellers in all three; the differences in coefficients between groups one and four are highl statisticall significant. During the bust period, interestingl, households with different wealth levels have similar tendencies to sell large cap, value, marginable stocks. Second, throughout our entire sample, the wealthiest households bet against short-term stock returns (so bet on short-term reversal), while all the other three groups chase short-term stock returns. Since the short-term contrarian strateg performs well in our sample period, this partle explains where the top household group outperforms the other three groups.

#### 5.2.1. Predicting stock returns in the cross-section

Our evidence in Section 4.2 alread suggests that wealthier households are more skilled at stock selection than the less wealth . Specificall , accounting for heterogeneit in portfolio composition more than doubles the magnitude of wealth redistribution between the bottom 85% and top 0.5% of households, compared to when we consider onl gains and losses resulting from market-level flows.

### A. Baseline Results

To formall examine investors' stock selection skills, we conduct Fama-MacBeth forecasting regressions of future stock returns on stock-specific capital flows b each of the four household groups, controlling for stock characteristics that are known to forecast stock returns. Panel A1 of Table 4 reports regression results with normalized capital flows from each household group as the onl explanator variables. The regression results show that capital flows b the bottom two household groups significant1 and negativel predict stock returns in the following week (we obtain similar results using returns in the next month). Capital flows of the largest household group, on the other hand, significant1 and positivel forecast future stock returns.<sup>23</sup> Panel A2 repeats the exercise b further controlling for the set of stock characteristics in Table A4. Across all specifications, the magnitude of the coefficient on *Flow* is at most 15% smaller in Panel A2 compared to the corresponding estimate in Panel A1. In other words, wealthier households have better stock selection skills than the less wealth over and be ond what is captured b observable firm characteristics.

We provide further evidence for the ultrawealth 's superior stock selection abilit using a calendar-time portfolio approach—that is, to track the dail returns to the equit portfolio of each household group.<sup>24</sup> As shown in Panel B of Table 4, relative to the CAPM model, the bottom 85% of all households earn a dail alpha of -13.2 bps (*t*-statistic = -5.01) in our 18-month sample, while the top 0.5% earn a dail alpha of 6.8 bps (*t*-statistic = 2.75). The difference between the two of 20.0 bps (*t*-statistic = 4.75), or over 50% a ear, is highl statisticall significant and can account for the majorit of the wealth redistribution documented in the previous section. Further controlling for the size and value factors in the Chinese market (following Liu et al., 2019), or using the DGTW adjustment (matching based on beta, size and the book-to-market ratio), has little impact on our result. Put different1, our documented wealth redistribution is not driven b households' differential exposures to common risk factors, but rather heterogeneit in their abilit to forecast firm-specific returns.

In Appendix Table A5, we repeat the exercise of Table 4 Panel A to examine the return predictabilit of trading b institutional and corporate investors. As can be seen from the last two columns of both panels in Table A5, institutional investors' trading at the stock level is a strong and positive predictor of stock returns in the following week; in contrast, corporate investors' trading does not forecast future individual stock returns.

#### B. Calm vs. Extreme Periods

Table 5 repeats the exercise in Table 4 for three additional periods: October 2014 to December 2015 (the bubble-crash period, Panel A), Jul 2014 to October 2014 (the mild-rise period, Panel B), and Januar 2012 to June 2014 (the calm period, Panel C). As shown in Panel A, the return predictabilit of trading b the bottom household group (per standard deviation of flows) in the bubble-crash period is -0.484 (*t*-statistic = -4.80) and that b the top household group is 0.444

<sup>&</sup>lt;sup>23</sup> Our documented return pattern is unlikel to be driven b flow-induced price pressure; untabulated results show that over longer horizons, the relation between capital flows b various household groups and the cross-section of average stock returns becomes statisticall insignificant but does not revert.
<sup>24</sup> To be consistent with our earlier tests, we onl consider positions that result from households' trading in our sample period—that is, to discard their initial holdings at the beginning of our sample.

#### Return Predictabilit of Flows and Calendar-Time Portfolios

This table anal zes the return predictabilit of trading b different household wealth groups in the bubble-crash period. Panels A1 and A2 report Fama-MacBeth regression results where the dependent variable is the future one-week stock return. The main independent variable of interest, Flow, is calculated as the stock-level capital flow in a given week, scaled b the average portfolio value of that investor group at the beginning and end of the same week. For ease of comparison, we normalize Flow b its standard deviation for each investor group. Panel A1 shows univariate regression results, and Panel A2 further controls for a batter of stock characteristics, including beta, firm size (size), book-to-market ratio (bm), a dumm variable indicating whether a stock is marginable (margin), and past returns at different horizons (over the past one, two, three, four weeks, as well as 2-to-6 months and 7-to-12 months). Panel B shows risk-adjusted dail returns of the calendar-time portfolios held b different wealth groups, with respect to the CAPM, Fama-French 3factor model, as well as DGTW-adjusted returns (controlling for size, value, and beta). We onl consider positions that result from households' trading in our sample period, therefore discarding their investors are classified into four groups according to initial holdings. Within the their total account value (equit in both Shanghai and Shenzhen Stock Exchanges + cash value): WG1 to WG4 include investors whose total account value fall into the brackets of <500K. 500K-3M, 3M-10M, and >respectivel . T-statistics, shown in brackets, are computed based on standard errors with Newe -West adjustments of four lags. \*, \*\*, and \*\*\* indicate statistical significance at the 10%, 5%, and levels, respectivel .

Panel B: Calend	ar-time	(dail ret)			
	WG1	WG2	WG3	WG4	WG4-WG1
CAPM alpha	-0.132	-0.087	-0.021	0.068***	0.200***
	[-5.01]	[-3.17]	[-0.82]	[2.75]	[4.75]
FF3 alpha	-0.124	-0.089	-0.025	0.059**	0.183***
	[-4.69]	[-3.22]	[-1.00]	[2.47]	[4.43]
	[-3.07]	[0.03]	[1.09]	[4.09]	[6.62]

(*t*-statistic = 6.20), with a difference of 0.928 (*t*-statistic = 7.94). Panel B conducts the same exercise for the mild-rise period. The return predictabilit of trading, again per standard deviation of flows, b the bottom household group in this period is -0.222 (*t*-statistic = -4.45) and that b the top household group is 0.180 (*t*-statistic = 5.83), with a difference of 0.401 (*t*-statistic = 4.06). Panel C shows the result for the calm period. The return predictabilit of trading b the bottom household group in the calm period is -0.118 (*t*-statistic = -5.24) and that b the top household group is 0.075 (*t*-statistic = 3.69), with a difference of 0.193 (*t*-statistic = 6.35).

In other words, the difference in flow-return predictabilit between the top and bottom household wealth groups in the bubble-crash period is more than twice as large as that in the mild-rise period, and more than four times as large as that in the calm period. In untabulated results, we further control for a large set of stock characteristics and continue to observe a two-to-four times larger flow-return relation in the extreme price-movement period than in the relativel calm periot the impact of heterogeneit in stock selection abilit on household

sector, holdings L. An, D. Lou and

150% before crashing 40%. Our administrative data include dail trading and holdings of all accounts in the Shanghai Stock Exchange, enabling us to examine wealth redistribution across the entire investor population.

Our anal ses reveal that the largest household accounts, those in the top 0.5% of the equit wealth distribution, activel increase their market exposures—through both inflows into the stock market and tilting towards high beta stocks—in the earl stage of the bubble period. The then quickl reduce their market exposures shortl after the market peak. Household accounts below the 85th percentile exhibit the exact opposite trading behavior. Over this 18-month period, the top 0.5% of households gain, while the bottom 85% lose, over 250B RMB, or about 30% of either group's initial account value. In stark comparison, the gains and losses experienced b the four household wealth groups are an order of magnitude smaller in the two-and-half ears prior to June 2014, when the market is relativel calm. Through the lens of a st lized portfolio choice model, we show that this wealth redistribution is unlikel to be driven b investors' rebalancing or trend-chasing trades and is instead more a reflection of the heterogeneit in households' investment skills (and possibl capital constraints).

Our finding that the largest 0.5% households gain much more than the bottom 85% in a boom-bust episode has implications for polic makers. It is widel believed that greater stock market participation is a path to prosperit and equalit, especiall in developing nations, where financial literac and market participation are generall low. However, if the poor, less financiall sophisticated end up investing activel in financial markets that are prone to bubbles and crashes, such participation can be detrimental to their wealth. This is particularl concerning given the recent finding that salient earl ear experiences can have long-lasting impact on **indiv**kiduals' economic decisions decades later. Consequentl,
